APPOROXIMATION BY GENERALIZED IMPEDANCE BOUNDARY CONDITIONS OF A TRANSMISSION PROBLEM IN ACOUSTIC SCATTERING

XAVIER ANTOINE\textsuperscript{1} AND HÉLÈNE BARUCQ\textsuperscript{2}

Abstract. This paper addresses some results on the development of an approximate method for computing the acoustic field scattered by a three-dimensional penetrable object immersed into an incompressible fluid. The basic idea of the method consists in using on-surface differential operators that microlocally reproduce the interior propagation phenomenon. This approach leads to integral equation formulations with a reduced computational cost compared to standard integral formulations coupling both the transmitted and scattered waves. Theoretical aspects of the problem and numerical experiments are reported to analyze the efficiency of the method and precise its validity domain.

Résumé. On s'intéresse dans ce travail au développement d’un modèle approché pour le calcul du champ acoustique diffracté par un obstacle pénétrable tridimensionnel immergé dans un fluide incompressible. L’idée de base de la méthode consiste à utiliser des opérateurs de surface différentiels qui reproduisent microlocalement les phénomènes de pénétration du champ. L’approche conduit à une formulation intégrale qui possède un coût réduit de calculs si on la compare à une formulation standard couplant les champs intérieur et extérieur. On aborde ici des aspects à la fois théoriques du problème et numériques pour analyser l’efficacité de l’approche et son domaine d’applicabilité.

1. INTRODUCTION

Since the advent of the Fast Multipole Method (FMM) [26], the technique of integral equations [15] has become one of the most efficient and useful methods in computational acoustics for solving the Helmholtz equation. Its principle consists in rewriting the initial problem as an equation set onto the surface of the considered object and leads to a gain of one dimension space. This equation is integro-differential and therefore non-local. If one considers the practical point of view of their numerical approximation by a boundary element method, the number of degrees of freedom $n_\lambda$ of the dense complex and generally non-hermitian linear system can be of several millions when the wavelength $\lambda$ of the incident signal is small compared to the size of the target. Instead of a direct Gauss elimination solver, the linear system is nowadays often solved by a Krylov subspace iterative solver (GMRES, CGS, QMR, etc...) [28]. Consequently, the total cost of a such algorithm to
get a sufficiently accurate solution is \( \mathcal{O}(n_\text{iter}^2 \varepsilon^2) \), where \( \mathcal{O}(n_\lambda^2) \) comes from the Matrix-Vector (MV) products involved at each step of the iterative solver and \( n_\text{iter} \) designates the number of iterations required to compute the solution with a tolerance \( \varepsilon \). The quadratic cost of a MV evaluation can actually be reduced to \( \mathcal{O}(n_\lambda \log n_\lambda) \) for instance by the FMM [18–20, 26]. The number of iterations \( n_\text{iter} \) can be diminished by using a suitable preconditioning strategy of the linear system [9, 10, 12] or the integral equation [5, 6, 13, 34].

Upstream from the problem of solving the linear system by a preconditioned Krylov/FMM solver is posed the question of the construction of an integral equation which gives an accurate computation of the scattered field and minimizes the size \( n_\lambda \) of the system. The present work is placed in this framework. More precisely, the problem under consideration here is the scattering of a time-harmonic acoustic wave by a three-dimensional bounded object \( \Omega_1 \) immersed into an incompressible fluid occupying the complementary domain \( \Omega_2 = \mathbb{R}^3/\Omega_1 \). The regular and arbitrarily shaped interface \( \Gamma \) between the two media is here supposed to coincide with the boundary of \( \Omega_1 \). The total field associated to the diffraction phenomenon is given as the solution to a transmission problem coupling two Helmholtz equations in each medium for two distinct frequencies \( k_1 \) in \( \Omega_1 \) and \( k_2 \) in \( \Omega_2 \). To numerically solve such a problem, one may solve a system of coupled equivalent integral equations [7, 15] set on \( \Gamma \). This provides an accurate solution [8, 17, 23]. However, the handling of two distinct domains defined by some different constitutive parameters involves two wavelengths: \( \lambda_1 \) and \( \lambda_2 \). The number of degrees of freedom is then fixed by the so-called “rule of the thumb” which corresponds to taking a certain number of points per wavelength. Therefore if \( |k_1| \gg |k_2| \), the size of the mesh is linked to the smallest wavelength \( \lambda_1 \). Moreover, this approach has also the drawback (see Section 2) of working with two surfacic densities: the two first traces \((p, \zeta)\) of the acoustic field at the interface. If we proceed to a boundary element approximation, the size \( n^{ex} \) of the resulting linear system for this exact formulation is \( 3N\lambda_1 \), where \( N\lambda_1 \) designates the number of vertices of the triangular mesh discretized with respect to the smallest wavelength \( \lambda_1 \).

A possible solution to work with only one surface field and to deal with a size \( n^{app} = N\lambda_2 \) which only depends on the exterior wavelength \( \lambda_2 \) (whence reducing drastically the size of the linear system since \( N\lambda_2 \ll N\lambda_1 \)) consists in replacing the exact interior integral equation by a localized approximate one proceeding to an asymptotic analysis in the high frequency regime assuming \( |k_1| \gg |k_2| \). This kind of equation is usually called a generalized impedance boundary condition [32] and can be written as

\[
\partial_n w = Zw, \quad \text{on } \Gamma,
\]

where \( Z \) is a differential operator including both the constitutive physical parameters and the geometrical characteristics of the scatterer \( \Omega_1 \). The simplest condition is the so-called Fourier-Robin boundary condition. It links the normal derivative and the trace of the exterior solution through a complex constant coefficient representing the surface impedance. It seems that the development of higher-order impedance boundary conditions has received less attention in acoustics than in electromagnetism [27, 29, 30, 32, 33, 37]. In 1992, Jones [22] has investigated an improvement of the On-Surface Radiation Conditions [24] method to construct generalized impedance boundary conditions for the Helmholtz equation in the case of a spherical interface. Next, Senior [31] derived approximate conditions for a flat interface. Recently, we have proposed in [4] a first and a second-order generalized impedance boundary conditions for the three-dimensional acoustic scattering problem by an arbitrarily shaped dissipative body. Using some explicit computations based on Mie series expansions in the case of both the circular cylinder and the spherical scatterer, it has been proved that the second-order condition yields a better accuracy and owns a wider physical and numerical domain of validity than the usual Fourier-Robin condition. The aim of this work is to extend the application range of the second-order generalized impedance boundary condition to a general scatterer by the way of an integral equation framework. It can be noticed that other kinds of numerical procedures may also be considered by using for instance a three-dimensional finite element method coupled to an efficient iterative solver and a non-reflecting boundary condition [3, 21].

The plan of the paper is the following. In Section 2, we fix the notations relative to the transmission acoustic scattering boundary-value problem. Next, we recall the derivation of the system of equivalent integral equations to solve and its boundary element approximation following [8]. In the third section, we introduce the approach based on the first and second-order generalized impedance boundary conditions derived in [4]. We state some
results on existence and uniqueness of the solution to the generalized impedance boundary-value problem under some physical and geometrical sufficient conditions. Next, we proceed to a numerical study of the validity domain of these two impedance conditions for a spherical scatterer. It appears that the numerical domain of application exactly coincides with the theoretical one formerly drawn to ensure the well-posedness. In a fourth section, we briefly describe the integral equation framework for the second-order generalized impedance boundary condition and focus on some aspects of its numerical implementation using boundary elements. This provides a numerical procedure with a cost close to the one usually required for the solution of a Neumann boundary-value problem in the exterior computational domain. Finally, we analyze the accuracy and computational cost of the exact and approximate integral equations to show the efficiency and sometimes also certain limitations of the proposed approach.

2. THE TRANSMISSION PROBLEM

2.1. Notations and problem setting

Let us consider a bounded domain $\Omega_1 \subset \mathbb{R}^3$ whose boundary $\Gamma$ is $C^\infty$ and the associated domain of propagation $\Omega_2 = \mathbb{R}^3 \setminus \overline{\Omega_1}$. We suppose that each medium $\Omega_j$, $j = 1, 2$, is homogeneous and isotropic. As a consequence, the density and sound velocity are two positive real constants respectively denoted by $\rho_j$ and $c_j$ for each domain $\Omega_j$. In the sequel, we make the assumption that $\Omega_1$ is a dissipative medium characterized by a real positive damping coefficient $\delta$.

Let $u_0$ be a complex-valued time-harmonic incident field defined in an open neighborhood $\mathcal{V}$ of $\Gamma$ and satisfying the Helmholtz equation

$$\Delta u_0 + k_2^2 u_0 = 0, \quad \text{in } \mathcal{V}.\nonumber$$

Hereabove, $k_2$ designates the wavenumber in the exterior domain. Such an equation results from removing the sinusoidal time dependence $e^{-ik_2 t}$ in the linear wave equation. The wavenumber $k_2$ is related to the pulsation $\omega$ by $k_2 = \omega/c_2$. A second wavenumber $k_1$ relative to the interior dissipative domain is defined as

$$k_1^2 = \frac{\omega^2}{c_1^2}(1 + \frac{i \delta}{\omega}). \tag{1}$$

A quite usual notation consists in introducing the complex refractive index $N$ and the complex contrast coefficient $\alpha$

$$N = \frac{1}{c_r}(1 + \frac{i \delta}{\omega})^{1/2}, \quad \alpha = \frac{1}{\rho_r(1 + i\delta/\omega)}, \tag{2}$$

where $c_r = c_1/c_2$ and $\rho_r = \rho_1/\rho_2$ respectively stand for the relative velocity and density. In the sequel, we denote by $z^{1/2}$ the principal determination of the square root of $z \in \mathbb{C}$ with branch-cut along the negative real axis. Therefore, the imaginary part of $N$ is strictly positive and $\alpha$ is a complex number whose real and imaginary parts are non-negative.

The scattered field $v$ satisfies the boundary-value problem

$$\begin{cases}
\Delta v_2 + k_2^2 v_2 = 0, & \text{in } \Omega_2, \\
\Delta v_1 + k_1^2 v_1 = k_2^2(1-N^2)u_0, & \text{in } \Omega_1, \\
[v] = 0 \quad \text{and} \quad [\chi \partial_n v] = -[\chi \partial_n u_0], & \text{on } \Gamma, \\
\lim_{|x| \to +\infty} |x| (\nabla v_2 \cdot \frac{x}{|x|} - ik_2 v_2) = 0,
\end{cases} \tag{3}$$

where the piecewise constant function $\chi$ is such that $\chi = 1$ in $\Omega_2$ and $\chi = \alpha$ in $\Omega_1$. Vector $n$ is the outwardly directed unit normal to $\Omega_1$. The restriction of the scattered field $v$ to $\Omega_j$, $j = 1, 2$, is denoted by $v_j := v|_{\Omega_j}$; notation $[\cdot]$ designates the jump through $\Gamma$ of a distribution defined in $\Omega_1 \cup \Omega_2$ and is given as the difference between the interior and exterior traces: $[v] := v_1|_{\Gamma} - v_2|_{\Gamma}$. If $a$ and $b$ are two complex-valued vector fields, their inner product is set as: $a \cdot b = \sum_{k=1}^3 a_k \overline{b_k}$. Operator $\nabla$ is the gradient operator of a scalar complex field.
and $\Delta$ designates the Laplace operator. Finally, the last condition in problem (3) is the well-known Sommerfeld radiation condition which ensures the uniqueness of the solution to the boundary-value problem. The notation $SRC(v)$ means that the given field $v$ satisfies the Sommerfeld Radiation Condition. We refer to Chazarain & Piriou [11] for any notation concerning the functional spaces (e.g. the Schwartz spaces $\mathcal{D}'(\Omega_1)$ or Sobolev spaces $H^1(\Omega_1)$ or $H^{1/2}(\Gamma)$). Here, $H^1_{\text{loc}}(\overline{\Omega_2})$ is the Sobolev space

$$\{ v \in H^1'((\Omega_2))/\varphi \in H^1(\overline{\Omega_2}), \forall \varphi \in \mathcal{D}([\mathbb{R}^3]) \}.$$ 

Under the above assumptions, we have the following existence and uniqueness result [4, 8].

**Theorem 2.1.** Let $f \in L^2(\Omega_1)$ and $g \in H^{-1/2}(\Gamma)$. Then, there exists a unique solution $v \in H^1(\Omega_1) \cap H^1_{\text{loc}}(\overline{\Omega_2})$ to the transmission boundary-value problem

$$\begin{cases}
\Delta v + k_0^2 v = f, \text{ in } \mathcal{D}'(\Omega_1), \\
\Delta v + k_1^2 v = 0, \text{ in } \mathcal{D}'(\Omega_2), \\
[v] = 0, \text{ in } H^{1/2}(\Gamma), \\
[\chi \partial_n v] = g, \text{ in } H^{-1/2}(\Gamma), \\
SRC(v) = 0.
\end{cases} \tag{4}$$

### 2.2. Integral equation formulation (IE)

Let $u = v + u_0$ be the total field in $\Omega_1 \cup \Omega_2$. Let us define the Green kernel $G_j$ associated to the Helmholtz equation in $\Omega_j$ by

$$G_j(x, y) := \frac{1}{4\pi} \frac{e^{ik_j|x-y|}}{|x-y|}.$$ 

We consider the following surface fields $p_j := u_j|\Gamma$ and $\zeta_j := \chi \partial_n u_j|\Gamma$, for $j = 1, 2$. Using the interface conditions arising from (4), the determination of the total field can be reduced to the computation of the quantities: $\zeta := \zeta_j$ and $p := p_j$. Let us consider the following integral operators on $\Gamma$

$$V_j \zeta(x) := \int_{\Gamma} G_j(x, y) \zeta(y) d\Gamma(y),$$

$$N_j p(x) := \int_{\Gamma} \partial_n(y) G_j(x, y) p(y) d\Gamma(y),$$

$$K_j \zeta(x) := N_j^T \lambda(x) = \int_{\Gamma} \partial_n(x) G_j(x, y) \zeta(y) d\Gamma(y),$$

$$D_j p(x) := \partial_n(x) \int_{\Gamma} \partial_n(y) G_j(x, y) p(y) d\Gamma(y),$$

where $x \in \Gamma$. The integral operators $V_j$, $N_j$ and $K_j$ are pseudodifferential operators of order $-1$ whereas $D_j$ is a first-order hypersingular operator (see e.g. [16]).

Let us introduce the product-space $Z = H^{-1/2}(\Gamma) \times H^{1/2}(\Gamma)$, $<\cdot, \cdot>$ the antiduality product between spaces $H^{1/2}(\Gamma)$ and $H^{-1/2}(\Gamma)$ and the integral operators

$$V := \alpha^{-1} V_1 + V_2, \quad N := N_1 + N_2, \quad K := K_1 + K_2, \quad D := \alpha D_1 + D_2.$$ 

We define the following integral operators

$$c_j(p, q) := \int_{\Gamma \times \Gamma} G_j(x, y) \text{curl}_g p(y) \cdot \text{curl}_g q(x) d\Gamma(y) d\Gamma(x), \quad j = 1, 2,$$

$$d_j(p, q) := k_j^2 \int_{\Gamma \times \Gamma} G_j(x, y) p(y) \overline{q(x)} n(y) \cdot n(x) d\Gamma(y) d\Gamma(x), \quad j = 1, 2,$$
and
\[ c(p, q) := ac_1(p, q) + c_2(p, q), \quad d(p, q) := ad_1(p, q) + d_2(p, q). \]
If \( \nabla \Gamma \) designates the surfacic gradient operator, the surfacic curling vector \( \text{curl}_\Gamma \) is given by \( \text{curl}_\Gamma \varphi = \nabla_\Gamma \varphi \times n \), for a distribution \( \varphi \in \mathcal{D}'(\Gamma) \). Let us define the sesquilinear forms
\[ a(\zeta, \mu) := < V \zeta, \mu >, \quad b(p, \mu) := < N p, \mu >, \quad b^*(\zeta, q) := < \nabla q, \zeta >. \]
Basing upon the approach of Bendali & Souilah [8], it can be shown that the solution to the boundary-value problem (4) can be calculated by solving the following system of integral equations
\[
\begin{align*}
\text{find } (\zeta, p) \in Z & \text{ solution to} \\
a(\zeta, \mu) - b(p, \mu) = & < u_0, \mu >, \quad \forall \mu \in H^{-1/2}(\Gamma), \\
b^*(\zeta, q) - c(p, q) + d(p, q) = & -< q, \nabla u_0 |\Gamma >, \forall q \in H^{1/2}(\Gamma).
\end{align*}
\]

2.3. The boundary element method

Let \( \Gamma_h \) be a polyhedral surface interpolating \( \Gamma \) and satisfying the classical overlapping condition involved in finite element methods [8, 14]. Let \( T_{h} = \bigcup_{i=1}^{NT} K_i \) be a triangulation of \( \Gamma_h \) where each triangle \( K_i \) satisfies: \( K_i \cap K_j = \emptyset \) for \( 1 \leq i \neq j \leq NT \). We denote by \( P_m \) the space of complex-valued polynomials of degree lower than or equal to \( m \). Then, we consider the finite element spaces
\[
\begin{align*}
M_h & := \{ \zeta \in L^2(\Gamma_h)/K := \zeta|K \in P_0, \forall K \in T_h \}, \\
V_h & := \{ q \in C^0(\Gamma_h)/K := q|K \in P_1, \forall K \in T_h \}.
\end{align*}
\]
We have \( \dim M_h = NT \) and \( \dim V_h = NV \), where \( NV \) denotes the number of vertices arising from the triangulation. If \( Z_h := M_h \times V_h \), the discrete solution \( (\zeta_h, p_h) \in Z_h \) satisfies the formulation (called IE during the numerical experiments at Section 4)
\[
\begin{align*}
a_h(\zeta_h, \mu_h) - b_h(p_h, \mu_h) = & < u_{0_h}, \mu_h >, \forall \mu_h \in M_h, \\
b^*_h(\zeta_h, q_h) - c_h(p_h, q_h) + d_h(p_h, q_h) = & -< q_h, \nabla u_{0_h}|\Gamma >, \forall q_h \in V_h,
\end{align*}
\]
where the discrete sesquilinear forms are given by: \( \forall (\zeta_h, \mu_h) \in M_h \times M_h \) and \( \forall (p_h, q_h) \in V_h \times V_h \)
\[
\begin{align*}
a_h(\zeta_h, \mu_h) & := \int_{\Gamma_h} \int_{\Gamma_h} \frac{1}{2} G_j(x_h, y_h) \zeta_h(y_h) \mu_h(y_h) d\Gamma_h(y_h) d\Gamma_h(x_h), \\
b_h(p_h, \mu_h) & := \int_{\Gamma_h} \int_{\Gamma_h} \partial_n G_j(x_h, y_h) p_h(y_h) \mu_h(y_h) d\Gamma_h(y_h) d\Gamma_h(x_h), \\
c_h(p_h, q_h) & := \int_{\Gamma_h} \int_{\Gamma_h} \chi G_j(x_h, y_h) \text{curl}_\Gamma p_h(y_h) \cdot \text{curl}_\Gamma q_h(x_h) d\Gamma_h(y_h) d\Gamma_h(x_h), \\
d_h(p_h, q_h) & := \int_{\Gamma_h} \int_{\Gamma_h} \chi k^2 G_j(x_h, y_h) p_h(y_h) q_h(x_h) \nabla_n(x_h) \cdot \nabla_n(y_h) d\Gamma_h(y_h) d\Gamma_h(x_h).
\end{align*}
\]
Before an assembling process, the numerical implementation involves elementary integrals which depend on quantities like \( \nabla_{\Gamma_h} p_h|\Gamma_h \) locally computed in a basis of each triangle \( K \) [1, 2, 35, 36]. In the case of some disjoint triangles, the integrals can be computed by a standard quadrature formula. For near interactions, a semi-numerical quadrature formula [1, 7] can be used. The convergence rate of the boundary element method is \( O(h^{1/2}) \) since a consistency error involves in the approximation of the exact surface by a polyhedral one. The size of the dense linear system associated to (5) is \((NT+NV)\). The solution to the linear system can be obtained by a Gauss elimination solver or more efficiently by a preconditioned subspace iterative solver accelerated by a Fast Multipole Method.
3. The generalized impedance boundary-value problem

3.1. The generalized impedance operators

Let us recall that the transmitted wave can be computed by the Helmholtz integral representation [15]

\[ \forall x \in \Omega_1, u_1(x) = \int_\Gamma (G_1(x,y)\zeta_1(y) - \partial_n G_1(x,y)p_1(y))d\Gamma(y). \]  

(6)

The above relation shows that the interior field can be determined by the interior Cauchy data \((\zeta_1, p_1)\). In other words, if the Steklov-Poincaré operator \(Z\) is known for the interior problem

\[ \zeta_1 = Zp_1, \quad \text{on } \Gamma, \]  

(7)

the solution \(u_1\) can be obtained by a simple calculation of \(p_1\) (\(\tilde{\zeta}_1\) being computed by Eq. (7)). Unfortunately, \(Z\) is a non-local pseudodifferential operator of order one. Therefore, no numerical gain is made comparatively to the exact integral approach. However, when the interior propagation phenomenon is such that the intensity of the internal field is essentially located near the boundary, the operator \(Z\) can be efficiently microlocalized by a high-frequency asymptotic analysis [4]. If \(Z_\ell\) denotes the differential operator of order \(\ell \in \mathbb{N}^*\) arising from the microlocalization of \(Z\), we can define the approximate densities \((\tilde{\zeta}_1, \tilde{p}_1)\) linked by the relation

\[ \tilde{\zeta}_1 = Z_\ell \tilde{p}_1, \quad \text{on } \Gamma. \]

The surface fields \((\tilde{\zeta}_1, \tilde{p}_1)\) are an approximation of the Cauchy data \((\zeta_1, p_1)\). For the sake of conciseness, we do not mention the dependence of \((\tilde{\zeta}_1, \tilde{p}_1)\) with respect to \(\ell\). In electromagnetism ([31–33]), the operators \(Z_\ell\) are generally called generalized impedance operators of order \(\ell\). They depend on the physical parameters \(\alpha, N\) and \(k_1\) but also on the geometry of the scatterer. In [4], we show that

\[ Z_\ell = -\text{div}_\Gamma (A_\ell \nabla_\Gamma) + \alpha_\ell I, \quad l = 1, 2, \]

where \(A_\ell\) is a tensor defined on the tangent plane \(T_x(\Gamma)\) and \(I\) is the identity operator of \(T_x(\Gamma)\). The operator \(\text{div}_\Gamma\) designates the surfacic divergence operator. We can define an approximation \((\tilde{\zeta}_2, \tilde{p}_2)\) of the exterior Cauchy data \((\zeta_2, p_2)\) by using the transmission conditions. The pair \((\tilde{\zeta}_2, \tilde{p}_2)\) then satisfies the relation

\[ \tilde{\zeta}_2 = Z_\ell \tilde{p}_2, \quad \text{on } \Gamma. \]  

(8)

Before giving the explicit form of \(Z_\ell\) for \(\ell = 1, 2\), let us introduce some useful notations linked to the geometry of the interface \(\Gamma\). Let \(\mathcal{R}\) be the curvature tensor. Its eigenvalues are the principal curvatures \(\kappa_1\) and \(\kappa_2\). More precisely, if \(R_1\) and \(R_2\) designate the principal curvature radii, we have \(\kappa_j = 1/R_j, j = 1, 2\). We define \(\mathcal{H} = (\kappa_1 + \kappa_2)/2\) as the mean curvature and \(\mathcal{K} = \kappa_1\kappa_2\) as the Gauss curvature. Finally, \(\Delta_\Gamma = \text{div}_\Gamma \nabla_\Gamma\) denotes the Laplace-Beltrami operator.

According to [4], the first-order condition corresponds to the choice \(A_1 := 0\) and \(\alpha_1 := -\alpha (ik_2 N + \mathcal{H})\) and the second-order one to

\[ \begin{align*}
A_2 & := -\alpha \left( \frac{1}{2ik_2 N} \left( I + \frac{i\mathcal{R}}{k_2 N} \right) \right), \\
\alpha_2 & := -\alpha \left( ik_2 N + \mathcal{H} \frac{1}{2ik_2 N} (\mathcal{H}^2 - \mathcal{K}) \left( 1 + \frac{2i\mathcal{H}}{k_2 N} \right) - \frac{1}{4k_2 N^2} \Delta_\Gamma \mathcal{H} \right).
\end{align*} \]

Remark 3.1. Higher-order differential operators can be constructed by a recursive process described in [4]. They should lead to more accurate approximations of the Cauchy data. However, they require the use of higher-order boundary element methods which can be difficult to numerically handle and penalize the computational
cost. An alternative solution consists in rather using some Padé approximants for computing the symbols of the expansion of the exact impedance operator. This possibility is examined in [3] but still requires further developments.

3.2. An existence and uniqueness result

The pair \((\tilde{\zeta}_2 - \partial_n u_{0|\Gamma}, \tilde{p}_2 - u_{0|\Gamma})\) defines a scattered field \(w_2\) through (6). Therefore, \(w_2\) satisfies the Helmholtz equation in the exterior domain of propagation \(\Omega_2\) and the Sommerfeld radiation condition at infinity. The natural question is now the following: if we can define \(w_{2|\Gamma}\) and \(\partial_n w_{2|\Gamma}\), do we have the two identifications \(w_{2|\Gamma} = \tilde{p}_2 - u_{0|\Gamma}\) and \(\partial_n w_{2|\Gamma} = \tilde{\zeta}_2 - \partial_n u_{0|\Gamma}\)? According to Eq. (8), we propose to define \(w_2\) as the solution to the boundary-value problem

\[
\begin{cases}
\Delta w_2 + k_2^2 w_2 = 0 & \text{in } \Omega_2, \\
(\partial_n - Z_I)w_2 = g_I & \text{on } \Gamma, \\
\lim_{|x| \to +\infty} |x| \left( \nabla w_2 - \frac{x}{|x|} - ik_2 w_2 \right) = 0.
\end{cases}
\]

In formulation (9), the source term \(g_I\) is given by: \(g_I = -(\partial_n - Z_I)u_0\). Let us prove that the boundary-value problem (9) admits a unique solution under some sufficient conditions.

In the case of the first-order condition \((A_1 := 0)\), the impedance operator is a zeroth-order operator. The boundary condition is a Fourier-Robin condition. The resulting boundary-value problem (9) is classical to solve by considering the space \(H^1_{\text{loc}}(\Omega_2)\). Since the boundary condition is a compact perturbation of the Neumann condition, the Riesz-Fredholm theorem applies and the existence of a solution is ensured providing the uniqueness only. The following result holds.

**Proposition 3.2.** Let \(g_I\) be given in \(H^{-1/2}(\Gamma)\). We assume that the mean curvature \(\mathcal{H}\) is positive. Then, the exterior boundary-value problem (9) related to the Fourier-Robin impedance boundary condition admits one and only one solution \(w_2\) in \(H^1_{\text{loc}}(\Omega_2)\) provided

\[
k_2 \mathcal{H}^{-1} \Im(N) > (1 + \frac{1}{2 \mathcal{H}^2 \Im(N)})^{-1}.
\]

**Proof.** We use a standard argument involving the Rellich lemma [25] to prove the uniqueness. Let \(B_R\) be a ball centered at the origin with a sufficiently large radius \(R\) to enclose \(\Omega_1\). Setting \(\Omega_R := \Omega_2 \cap B_R\), we get

\[
\int_{\Omega_R} (\Delta w_2 + k_2^2 w_2) \overline{w_2} \, d\Omega_R = 0.
\]

By using the usual Green formula, the above variational equation modifies to

\[
\int_{\Omega_R} \left( k_2^2 |w_2|^2 - |\nabla w_2|^2 \right) \, d\Omega_R = \int_{\Gamma} \partial_n w_2 \overline{w_2} \, d\Gamma - \int_{S_R} \partial_r w_2 \overline{w_2} \, dS_R,
\]

where \(S_R := \partial B_R\) denotes the boundary of \(B_R\). Since the integral on \(\Omega_R\) is real, we get

\[
\Im \int_{\Gamma} \partial_n w_2 \overline{w_2} \, d\Gamma = \Im \int_{\Gamma} \partial_n |w_2|^2 \, d\Gamma = \Im \int_{S_R} \partial_r w_2 \overline{w_2} \, dS_R.
\]

Let us remark that \(\Im(-\alpha_1) = k_2 \Re(\alpha N) + \mathcal{H} \Im(\alpha), \Re(\alpha N) > 0\) and \(\Im(\alpha) < 0\). It results that the imaginary part of \(\alpha_1\) is negative if

\[
k_2 \Re(\alpha N) + \mathcal{H} \Im(\alpha) > 0 \iff k_2 > -\mathcal{H} \frac{\Im(\alpha)}{\Re(\alpha N)}.
\]
Noticing that \( \Re(\alpha) = -\gamma_1^{-1}\Im(\alpha) \), with \( \gamma_1 = \delta/\omega \), we conclude that \( \Re(\alpha N) = -\Im(\alpha)\Im(N) + \gamma_1^{-1}\Re(N) \). As a consequence, inequality (11) reads
\[
k_2 > \frac{\mathcal{H}}{\Im(N) + \gamma_1^{-1}\Re(N)}.
\]
Moreover, using the definition of the refractive index \( N \), a simple calculation gives: \( \Re(N)\Im(N) = \gamma_1/(2c^2) \). Therefore, relation (11) can be simplified as
\[
k_2\Im(N)\mathcal{H}^{-1} > (1 + \frac{1}{2c^2\Im^2(N)})^{-1}.
\]
Consequently, since we get
\[
\text{Im} \int_{S_R} \partial_r w_2 \overline{w_2} \, dS_R \leq 0,
\]
the uniqueness is then classically obtained by using the Sommerfeld condition and the Rellich lemma. \( \square \)

In [4], we describe how to approximate the Steklov-Poincaré operator in a consistent way for the interior problem by an asymptotic analysis with respect to the high-frequency parameter \( |k_1| = k_2|N| \gg 1 \). In this approach, another possibility is to consider a high refraction index \( N \), i.e. \( |N| \gg 1 \), to get the same generalized impedance boundary conditions. As a consequence, condition \( |N| \gg 1 \) is a first condition to impose to ensure the validity of the approximation of the transmission acoustic scattering problem using an impedance boundary condition. Moreover, as proposed in proposition 3.2, a sufficient condition to have a well-posed problem is
\[
k_2\Im(N)\mathcal{H}^{-1} > (1 + \frac{1}{2c^2\Im^2(N)})^{-1}.
\]
Hence, the existence and uniqueness to the approximate problem is proved if
\[
k_2\Im(N)\mathcal{H}^{-1} > (1 + \frac{1}{2c^2\Im^2(N)})^{-1} \text{ and } |N| \gg 1.
\]

In the numerical study of the validity of the approximate model using a Fourier-Robin (order 1/2) boundary condition
\[
\partial_n w_2 + i\alpha k_2 N w_2 = g_{1/2}, \quad \text{on } \Gamma,
\]
in the context of two-dimensional electromagnetism, Wang [32,37] has given two quantitative validity conditions of the model
\[
k_2 R\Im(N) > C_1 \quad \text{and} \quad |N| > C_2,
\]
for a circular cylinder \( \Omega \) of radius \( R \). The real positive constants \( C_1 \) and \( C_2 \) are obtained by fixing a tolerance on the computation of the far-field. These relations have next been extended to a second-order generalized impedance boundary condition by Senior & Volakis [32]. To the best of the authors’ knowledge, no theoretical justification on the origin of conditions (15) has been given. Moreover, these conditions have been extrapolated in the framework of the three-dimensional acoustics. A possible explanation is that only the Fourier-Robin boundary condition (14) is usually used in acoustics. However, this condition does not take the geometry of the scatterer into account. When the well-posedness of the boundary-value problem is examined, then only conditions involving the physical parameters of the problem are needed during the proof of the existence and uniqueness result [31]. Hence, conditions (13) can be seen as a qualitative justification of Wang’s conditions (15) extended to the case of the acoustic scattering by an arbitrarily shaped convex body.

The second-order impedance boundary condition is defined by the operator \( Z_2 \). The boundary-value problem is a non-standard scattering problem (sometimes also called a Ventcel problem). A well-adapted functional framework is given by the Fréchet space \( H^{1,1}_{\text{loc}}(\Omega, \Gamma) = \{ u \in H^{1,1}_{\text{loc}}(\Omega), \quad u|_\Gamma \in H^1(\Gamma) \} \). According to [36], one gets the following theorem.
A direct calculation gives

Moreover, we suppose that

Hence, we deduce that if

which can be further reduced to

the uniqueness of the solution if

Without any specific hypothesis, we have already seen that it is sufficient to fulfill that

Proof. We have already assumed that it is sufficient to fulfill that \( \Im(A_2(x) \xi \cdot \xi) \leq 0 \), \( \forall \xi \in \Omega \), \( \forall x \in \Gamma \), and \( \Im(\alpha_2(x)) \leq 0 \), \( \forall x \in \Gamma \).

Thus, the well-posedness of problem (9) is ensured provided \( A_2 \) and \( \alpha_2 \) satisfy conditions (16). As far as the numerical solution of (9) is concerned, we intend to consider the conditions involving (1)-(2). The following proposition holds.

**Proposition 3.4.** Let us assume that \( \Omega_1 \) is a convex domain and that we have the inequality

Moreover, we suppose that \( \gamma_1 \in ]\sqrt{3}, +\infty[ \). Then, conditions (16) are satisfied provided

and

Proof. We have already seen that it is sufficient to fulfill that \( \Im(A_2 \xi \cdot \xi) \leq 0 \). If \( \Omega_1 \) is convex, the eigenvalues of the curvature operator \( \mathcal{R} \) are positive and we have \( \mathcal{R} \xi \cdot \xi \geq 0 \). Moreover, a straightforward calculation yields

Without any specific hypothesis, \( \Im(\alpha/N^2) \) is negative and we get

Hence, we deduce that if \( \gamma_1 \in ]0, \sqrt{3}[ \), then we have: \( \Im(A_2(x) \xi \cdot \xi) > 0 \). This implies that we cannot ensure the uniqueness of the solution if \( \gamma_1 \in ]0, \sqrt{3}[ \). It does not mean that the solution is not unique since the inequality \( \Im(A_2(x) \xi \cdot \xi) \leq 0 \) is only a sufficient condition. However, we will later see that the case \( \gamma_1 \in ]0, \sqrt{3}[ \) (corresponding to a weak absorbing medium) yields an inaccurate approximate model. Therefore, we restrict our attention to the case \( \gamma_1 \in ]\sqrt{3}, +\infty[ \). Then, \( \Im(A_2(x) \xi \cdot \xi) \leq 0 \) if and only if we have

A direct calculation gives \( \Im(\alpha N^{-2}) = \Re(\alpha) \Im(N^{-2}) + \Im(\alpha) \Re(N^{-2}) \). Since \( \Re(\alpha) = -\gamma_1^{-1} \Im(\alpha) \), we get

which can be further reduced to

\[
\Im\left(\frac{\alpha}{N^2}\right) = \frac{2 \Im(\alpha)}{c^2 |N|^2}
\]
using $\Re(N^2) = \gamma_1^{-1}\Im(N^2)$ and $\Im(N^2) = \gamma_1/c_2^2$. Let us consider now the term $\Re(\alpha/N)$. Using

$$
\Re(\frac{\alpha}{N}) = \frac{1}{|N|^2}(\Re(\alpha)\Re(N) + \Im(\alpha)\Im(N)),$$

$\Re(\alpha) = -\gamma_1^{-1}\Im(\alpha)$ and $2c_2^2\Im(N) = \gamma_1(\Re(N))^{-1}$, we obtain

$$
\Re(\frac{\alpha}{N}) = \frac{\Im(\alpha)\Im(N)}{|N|^2}(1 - \frac{1}{2c_2^2\Im(N)}).
$$

(22)

Then, by plugging (21) and (22) into (20) when $\gamma_1 \in [\sqrt{3}, +\infty]$, we see that $\Im(A_2(x)|\xi, \overline{\xi}) \leq 0$ if and only if the following inequality holds

$$
k_2\Im(N) \min_{x \in \Gamma} R_j(x) > \frac{2}{c_2^2|N|^2}(1 - \frac{1}{2c_2^2\Im(N)})^{-1}.
$$

Let us study the sign of $\alpha_2$. Since $\Im(\alpha N^2)$ and $\Im(\alpha/N^2)$ have the same signs, the following inequality holds

$$
\Im\left(\frac{\alpha}{\Gamma^2}\right) (\frac{\Delta N}{4} + \mathcal{H}(\mathcal{H}^2 - \mathcal{K})) \leq 0,
$$

under the assumption: $\Delta N/4 + \mathcal{H}(\mathcal{H}^2 - \mathcal{K}) \geq 0$. Hence, the inequality $\Im(\alpha_2) \leq 0$ is satisfied if we have

$$
\Re(\alpha N)k_2^2 + \mathcal{H}\Im(\alpha)k_2 + \frac{(\mathcal{H}^2 - \mathcal{K})}{2}\Re(\frac{\alpha}{N}) \geq 0.
$$

(23)

Now, let us observe that $\Re(\alpha N)$ and $\Re(\alpha/N)$ have the same signs. Hence, if $\gamma_1 \in [\sqrt{3}, +\infty]$, Eq. (23) is equivalent to

$$
P(k_2) = k_2^2 + \frac{\mathcal{H}m(\alpha)}{\Re(\alpha N)}k_2 + \frac{(\mathcal{H}^2 - \mathcal{K})}{2\Re(\alpha N)} \Re(\frac{\alpha}{N}) \geq 0.
$$

A computation of the discriminant $D$ associated to the above polynomial $P$ shows that $D > 0$ if $\gamma_1 \in [\sqrt{3}, +\infty]$. Hence, $P$ admits two distinct real roots $k_2^+$ of opposite sign. The positive root $k_2^+$ is given by

$$
k_2^+ = \sqrt{\frac{\mathcal{H}\Im(\alpha)}{2\Re(\alpha N)}(1 + (1 - \frac{2(\mathcal{H}^2 - \mathcal{K})\Re(\alpha N^{-1})\Re(\alpha N)}{\mathcal{H}^2\Im(\alpha)})^{1/2})}.
$$

(24)

Some simple calculations allow to show that

$$
\Re(\alpha N)\Re(\frac{\alpha}{N}) = \Re(\alpha)^2\Re(N)\Re(\frac{1}{N}) + \Im(\alpha)^2\Im(N)\Im(\frac{1}{N}) = \Re(\alpha)\Re(\frac{\alpha}{N})[\Im(N)\Re(\frac{1}{N}) + \Im(\frac{1}{N})\Re(N)].
$$

Moreover, since $-\gamma_1\Re(\alpha) = \Im(\alpha)$, we also have

$$
\frac{\Re(\alpha N)\Re(\alpha N^{-1})}{\Im(\alpha)^2} = \frac{1}{\gamma_1^2}\Re(N)\Re(\frac{1}{N}) + \Im(N)\Im(\frac{1}{N})].
$$

Finally, since $\Re(1/N) = \Re(N)/|N|^2$ and $\Im(1/N) = -\Im(N)/|N|^2$, we get

$$
\frac{\Re(\alpha N)\Re(\alpha N^{-1})}{\Im(\alpha)^2} = \frac{\Im(\alpha)^2}{|N|^2}(1 - \frac{1}{4c_2^2\Im(N)}).
$$

Therefore, (24) is satisfied if $k_2 \geq k_2^+$ or in other words if

$$
k_2\mathcal{H}^{-1}\Im(N) > \frac{1}{2}(1 + \frac{1}{2c_2^2\Im(N)})^{-1}\left(1 + \sqrt{\frac{2(\mathcal{H}^2 - \mathcal{K})\Im(N)^2}{\mathcal{H}^2|N|^2}(1 - \frac{1}{4c_2^2\Im(N)})}}\right).
$$
In the case of a sphere, the condition (18) associated to the second-order condition is identical to the one obtained for the first-order condition and condition (17) is fulfilled. For a regular surface, quantity $(\mathcal{H}^2 - \mathcal{K})/\mathcal{H}^2 = (\kappa_1 - \kappa_2)^2/\left(\kappa_1 + \kappa_2\right)^2$ is generally quite small and always lower than 1. Similarly, expression $\Im(N)^2/|N|^2$ is inferior to 1. Hence, condition (18) is not much more restrictive than (10). Condition (19) is not so restrictive as it looks like. Indeed, the approximate model is associated to some physical parameters such that $\Im(N) \gg 1$ and $|N| \gg 1$. This implies that in (19), the right hand-side tends to be small while the left hand-side is relatively large. If we compare the sufficient conditions in Propositions 3.2 and 3.3, it seems at first sight that the second-order condition is more restrictive than the first-order one. However, these conditions must be coupled with the asymptotic one: $|N| \gg 1$. Hence, the conditions of Proposition 3.3 are satisfied for a larger range of parameters $(k_2, N, \alpha)$ than in Proposition 3.2. We will see in the following section that the same conclusion holds when considering the validity domain of each impedance boundary condition. Finally, condition $\gamma_1 \geq \sqrt{3}$ must be satisfied when applying the second-order condition to obtain a sufficiently small error. From a practical point of view, it is not a real restriction as seen in the following Section.

### 3.3. Numerical validity domain

It is not surprising that the impedance boundary-value problem approximates the exact problem with a good accuracy for a suitable set of parameters. Indeed, the impedance boundary condition arises from an approximation of an exact condition. This approximation is justified for a sufficiently absorbing object [4]. In this situation, the main part of the energy of the interior field is localized near the interface. Therefore, the microlocalization of the exact boundary operator is valid and leads to an accurate approximate operator.

To precise the validity domain of the method, we consider the scattering problem of a plane wave $u_0$ which strikes the unitary ball centered at the origin. More precisely, we take $u_0 = \exp(-ik_2 x_1)$. We define the far-field pattern given by the Radar Cross Section (RCS)

$$\text{RCS}(\theta) = 10\log_{10}(4\pi|a(\theta)|^2) \text{ (db)},$$

where $a(\theta)$ denotes the diffusion amplitude of the scattered field in the direction $\theta = (\cos\theta \cos\phi, \sin\theta \cos\phi, \sin\phi)$, setting $(\theta, \phi)$ as the spherical angular coordinates on the unit sphere. We represent the relative error on the RCS for the $L^2(S_R)$-norm, where $S_R$ designates the sphere centered at the origin and with a radius $R$ large enough to have a suitable representation of the far-field.

Let us choose $c_r = 0.75$, $\rho_r = 1.2$ and $\gamma_1 = 2$. The frequency $k_2$ is equal to 15. On Fig. 1, we can observe that the bistatic RCS is more accurate for the second-order condition (the relative error is 0.5%) than for the first-order one (a relative error of 11.6%). Similar results have been reported in [4].

Now, we want to compute an approximate RCS with an error lower than 2%. On Fig. 2, we represent the evolution of the relative error according to $k_2$ (for $c_r = 0.75$, $\rho_r = 1.2$ and $\gamma_1 = 2$). We see that the approach is a high-frequency method: the error decreases as the wavenumber increases. Moreover, we can observe that the first-order impedance boundary condition leads to a relative error on the RCS which stabilizes around 10%. In the case of the second-order condition, the relative error is lower than 2% as soon as $k_2 \geq 6.6$.

We consider on Fig. 3 the variations of the error with respect to the relative velocity $c_v$. To this end, we take $k_2 = 6.6$, $\rho_r = 1.2$, $\gamma_1 = 2$. The quality of the approximate solution is better as $c_v$ decreases. To get an error lower than 2%, we see that $c_v$ must be lower than 0.4 for the first-order condition and than 0.75 for the second-order condition. In fact, the relative velocity $c_v$ is equal to $c_1/c_2$, where $c_1$ and $c_2$ are respectively the velocity in the scatterer and in the external medium. In both cases, the accuracy of the method is guaranteed as long as $c_1$ is strictly lower than $c_2$. We have already mentioned the fact that the proposed approach is valid in the case where the interior propagation is mainly localized near the interface $\Gamma$. This is effectively the case when $c_1/c_2 \ll 1$: $c_v$ must be small enough to ensure a good accuracy. This last point was already emphasized in proposition 3.4 fixing any of the parameters and varying $c_v$. This latter parameter must be small enough to
get the uniqueness of the approximate solution. A wider applicability of the second-order condition compared to the first-order condition is observed.

We consider now the relative error as a function of $\rho_r$. Let us fix $k_2 = 6.6$, $c_r = 0.75$, $\gamma_1 = 2$. We observe on Fig. 4 that the relative error is maximal (around 2%) for $\rho_r = 1.3$ for the second-order condition. In the case of the first-order condition, the error is relatively important for any value of $\rho_r$. We observe that the influence of the relative density on the error is not really significant for the second-order condition.

Finally, we consider that $\gamma_1$ varies and we choose $k_2 = 6.6$, $c_r = 0.75$ and $\rho_r = 1.2$. Fig. 5 shows that the relative error decreases as $\gamma_1$ increases. Moreover, the error is lower than 2% for the second-order condition.
when $\gamma_1 \geq 1.7$. This is a very interesting property since we have proved that the problem is well-posed when $\gamma_1 > \sqrt{3} \approx 1.73$.

The validity analysis makes our previous theoretical study consistent. We obtain a condition linking $k_2$, $N$ and the dimensions of the scatterer to get an error lower than 2% for a given impedance condition. For the first-order condition, we have $k_2 R^3(N) \geq 13.9$ and $|N| \geq 3.8$, while for the second-order condition we show that $k_2 R^3(N) \geq 7$ and $|N| \geq 2$. Such conditions are similar to those involved for the well-posedness of the approximate boundary-value problem. Moreover, they are close to the conditions originally derived for the two-dimensional problems [32].
Two significant aspects result from this analysis. The first interesting point is that one can construct an integral equation involving only one unknown surface field, the second one being determined by the impedance condition. Secondly, we see that the use of the microlocal analysis is efficient if \(|k_1|\) is large enough. In this situation, a method which would only require the solution to the exterior boundary-value problem would be interesting for high interior wavenumber. Indeed, in this case, one would have in almost situations a larger wavelength \(\lambda_2\) in the exterior domain. Since the size of the mesh involved during the approximation of an integral equation is a fraction of the smallest wavelength, one can expect to have a better convergence of a numerical method for solving the approximate model rather than for the exact problem at a given resolution.

Since the second-order condition is more efficient, we focus our study on this condition in the above section.

4. INTEGRAL EQUATION FORMULATION AND NUMERICAL EXPERIMENTS

This section is devoted to the study of an integral formulation which makes use of the microlocal generalized impedance boundary operator. In a first part, we present the formulation that we designate by Combined Micro-Integral Equation (CMIE) for the sake of conciseness. In a second part, its numerical approximation is described precisely its numerical advantages as compared to the standard Integral Equation (IE) method. We finally report some numerical tests. As in the case of a spherical scatterer, the CMIE method gives accurate results for an ellipsoidal scatterer and provides an interesting alternative to the fully coupled IE formulation.

4.1. The integral equation formulation (CMIE)

The selected strategy is based on the integral formulation proposed by Vernhet [35, 36]. To this end, we introduce \(w_1\) as the solution to the non-standard interior boundary-value problem associated to (9). Let us define \(w\) by: \(w_{|\Omega_j} := w_j\), for \(j = 1, 2\). We also consider the densities \(\tilde{m} \in H^{-1/2}(\Gamma)\) and \(\tilde{j} \in H^1(\Gamma)\) and the Lagrange multiplier \(\tilde{l} \in H^1(\Gamma)\)

\[
\tilde{m} := [\partial_n w], \quad \tilde{j} := [w] \quad \text{and} \quad \tilde{l} := \frac{w_1 + w_2}{2}.
\]

Following [35, 36], a suitable Fredholm integral formulation of the first kind adapted to problem (9) (and called here Combined Micro-Integral Equation (CMIE)) consists in finding \((\tilde{m}, \tilde{j}, \tilde{l}) \in \Theta\) solution to the saddle point
problem
\[
\tilde{a}(\tilde{m}, \tilde{j}, (m, j)) + \int_{\Gamma} l(m - Z_2^j) d\Gamma = \int_{\Gamma} g_2 j d\Gamma,
\]
(25)
where \(\Theta\) is the product space defined by \(\Theta := H^{-1/2}(\Gamma) \times H^1(\Gamma) \times H^1(\Gamma)\). The bilinear form \(\tilde{a}(..)\) is such that
\[
\tilde{a}(\tilde{m}, \tilde{j}, (m, j)) := - < V_2 \tilde{m}, m > + < N_2 \tilde{j}, m > + < N_2 \tilde{j}, \tilde{m} > + < D_2 \tilde{j}, \tilde{j} >,
\]
with \(< D_2 \tilde{j}, \tilde{j} > := c_2(\tilde{j}, j) - d_2(\tilde{j}, j)\) and
\[
\int_{\Gamma} l Z_2^j d\Gamma = A_2(\tilde{j}, l) := \int_{\Gamma} (A_2 \nabla \Gamma \cdot \nabla \tilde{j} + \alpha_2 \tilde{j}) d\Gamma.
\]
The existence and uniqueness of the solution to system (25) is based on the statement of a Babuška inf-sup condition.

4.2. Boundary element approximation and numerical experiments

The boundary element approximation of the unknown fields is given by \((\tilde{m}, \tilde{j}, \tilde{l})\) in \((V_\lambda)^3\). At first sight, the dimension of the approximation space is triple compared to the one required for a Neumann problem. Fortunately, a mass lumping process [35, 36] allows to avoid this problem by keeping the dimension of the approximation space is triple compared to the one required for a Neumann problem. This aspect is observed in the section below. A difficulty concerns the construction of a suitable \(P_1\)-approximation of the curvature tensor \(\mathcal{R}\) in a basis of the tangent plane at a node of the mesh. To this end, we adapt the approach established in [2]. Some numerical experiments (not reported here) using formulation (25) show that the theoretical rate of convergence [35, 36] \(O(h^{1/2})\) of the CMIE is not affected by the approximation of \(\mathcal{R}\).

The benchmark computations are given by the exact solution computed by its Mie series for the unit sphere or by the IE (with a sufficiently refined mesh) otherwise. The first test case consists in illuminating the unit sphere by an incident plane wave of direction \(\theta = (-1, 0, 0)\) at a frequency \(k_2 = 15\). The physical parameters are \(c_r = \rho_r = 1.5\) and \(\gamma_1 = 10\). The RCS computations are depicted on Fig. 6. The relative quadratic error on the RCS between the two exact (Mie) solutions is 0.1%. This ensures the validity of the approximate method. For a given resolution, the size \(NV_{\lambda_2}^{\text{CMIE}}\) of the linear system associated to the CMIE is three times smaller than the size \(NV_{\min(\lambda_1, \lambda_2)}^{\text{IE}}\) of the system issued from the discretization of the IE formulation. This reduction of the computational cost is due to the mass lumping process arising from the boundary element method. Now, let us analyze the influence of the mesh resolution on the convergence of the integral methods. We present on Table 1 the quadratic relative error on the RCS for several meshes. It appears that the CMIE formulation has a better convergence rate than the IE formulation. Moreover, the IE approach requires a very small meshsize to get a satisfactory accuracy. These observations are completely in accordance with the above remarks concerning the wavelength dependence of the sizes \(NV_{\lambda_2}^{\text{CMIE}}\) and \(NV_{\min(\lambda_1, \lambda_2)}^{\text{IE}}\) of the matrices. Indeed, we have considered a smaller wavelength in the interior domain \((|k|_1 = 30)\) than in the exterior domain \((k_2 = 15)\). Hence, the CMIE method seems very attractive in the case of a high refraction coefficient.

We consider on Fig. 7 a second test case: the scattering of a plane wave of incidence \(\theta = (-1, 0, 0)\) and wavenumber \(k_2 = 10\) by an ellipsoidal scatterer centered at the origin and with semi-axis \(a = 1, b = 0.5\) and \(c = 0.3\) respectively along \((Ox_1), (Ox_2)\) and \((Ox_3)\). The obstacle is characterized by the physical constants
Figure 6. Computation of the RCS (db) by the IE and CMIE methods for the unit sphere.

$r = 1.1$, $c_r = 1.2$ and $\gamma_1 = 5$. We consider that the reference IE solution is given for $NE = 3000$ edges. As it can be observed, a good accuracy is obtained for the IE method with $NE = 1080$ edges. The CMIE method converges towards the reference solution a little bit more slowly than the IE method. This is due to the limit of validity of the microlocal condition which penalizes the accuracy of the integral method and becomes prevailing. To precise the convergence of the method, we depict on Table 2 the quadratic relative error on the

RCS according to the mesh refinement. Despite this lower convergence, we must always have in mind that the size of the linear system related to the CMIE method is three times smaller than for the IE method. This finally makes the method competitive.
